Abstract

The one dimensional dilute Kondo lattice model is investigated by means of bosonization for different dilution patterns of the array of impurity spins. The physical picture is very different if a commensurate or incommensurate doping of the impurity spins is considered. For the commensurate case, the obtained phase diagram is verified using a non-Abelian density-matrix renormalization-group algorithm. The paramagnetic phase widens at the expense of the ferromagnetic phase as the f-spins are diluted. For the incommensurate case, antiferromagnetism is found at low doping, which distinguishes the dilute Kondo lattice model from the standard Kondo lattice model.

Heavy fermion systems have been of great theoretical interest since their discovery some twenty years ago.[1] The central problem posed by heavy fermion materials is to understand the interaction between an array of localized moments (generally f - electrons in lanthanide or actinide ions) and conduction electrons (generally s - or d - band). This situation is well described by an antiferromagnetically coupled Kondo type model.

The solution of Kondo type models is well understood in two limiting cases; the single impurity limit[2] which can be reduced to a one dimensional problem and solved via Bethe Ansatz, and secondly the Kondo lattice model (KLM), which was solved via bosonization[3,4] and numerous numerical approaches[5,6] in one dimension for half - and partial conduction band - filling. For half - filling the results indicate the existence of a finite spin and charge gap. Accordingly in this case the Kondo lattice model is an insulator with well defined massive solitonic excitations of the spin sector.

For partial conduction band filling, the conduction electrons form a Luttinger liquid, with spin and charge separation.[3,6] The localized spins, however, exhibit ferromagnetism, due to an effective double exchange coupling.[4,5] The double exchange is driving the system toward ferromagnetism, while the fluctuations generated by Kondo singlets compete against this tendency. As a consequence, the paramagnetic to ferromagnetic phase transition is of the quantum order - disorder type, typical to models with an effective random field.[4] However, for small Kondo coupling and close to half filling an RKKY liquid state and polaronic regime are always present.[5]

Beyond these two solvable limits, no rigorous results exist for the intermediate cases, where the number of impurities are neither one, nor equal to the number of sites. This is the focus of our study. We concentrate on the one dimensional case, and start from the Kondo lattice limit introducing impurity spin *holes*, that is we will be dealing with a *dilute* Kondo lattice model (DKLM):

$$H \;=\; -t\sum_{i=1,\sigma}^{L-1}(c^{\dagger}_{i,\sigma}c_{i+1,\sigma}+\text{h.c.})\;+\;J\sum_{i=1}^{L}\mathcal{P}\,\mathbf{S}^c_i\cdot\mathbf{S}_i\,\mathcal{P}\;, \tag{1}$$

where L is the number of sites and $t>0$ is the conduction electron hopping. We measure the Kondo coupling J in units of the hopping t. We denote by N_f ($n_f = N_f/L$) the number (concentration) of impurities and N_c ($n_c = N_c/L$) the number (concentration) of conduction electrons. The constraint $N_f \leq L$ is imposed by $\mathcal{P}$, which is an operator that projects out a pre-determined set of f-spins. $\mathbf{S}_i$ are spin 1/2 operators for the localized spins, e.g. f, and

$\mathbf{S}_i^c = \frac{1}{2}\sum_{\sigma,\sigma'} c^\dagger_{i,\sigma}\boldsymbol{\sigma}_{\sigma,\sigma'}c_{i,\sigma'}$ with $\boldsymbol{\sigma}$ the Pauli spin matrices and $c^\dagger_{i,\sigma}$, $c_{i,\sigma}$ the electron creation and annihilation site operators.

We investigate the behavior of the DKLM both by an analytical approach, based on a standard bosonization scheme, and by numerical calculations. The latter were performed using the newly developed non-Abelian density-matrix renormalization-group (DMRG) algorithm,[7] which preserves the total spin and pseudospin symmetry. This choice of basis first of all greatly facilitates the observation of magnetic phases and secondly it gives a dramatic performance improvement compared to the standard DMRG basis.

The bosonization we use takes the standard approach[8] by first decomposing the on-site operators into Dirac fields, with spinor components $\tau = \pm$ (otherwise known as the right, $\tau = +$, and left, $\tau = -$, movers): $c_{x,\sigma} \approx \sum_\tau c_{\tau,x,\sigma} \equiv \sum_\tau e^{ik_F x}\Psi_{\tau,\sigma}(x)$, where $k_F = \pi n_c/2$ and we consider the lattice spacing to be unity. Next we bosonize the Dirac fields with $\Psi_{\tau,\sigma} = \exp(i\Phi_{\tau,\sigma})/\sqrt{2\pi\lambda}$, where $1/\lambda$ is the ultraviolet cutoff. For the scalar Bose fields, $\Phi_{\tau,\sigma}(x)$ and its canonical conjugate momenta, $\Pi_{\tau,\sigma}(x)$, $\Phi_{\tau,\sigma}(x) = \int_{-\infty}^{x} dx'\Pi_{\tau,\sigma}(x')$, we use the standard Mandelstam representation,[9] which introduces a momentum cutoff function $\Lambda(k) = \exp(-\lambda|k|/2)$ via the Fourier transforms. Thus, the electron field can be represented in terms of collective density operators which satisfy Bose commutation relations:

$$c_{\tau,x,\sigma} \approx \exp(i\tau k_F x)\, \exp i\{\theta_\rho(x) + \tau\phi_\rho(x) + \sigma[\theta_\sigma(x) + \tau\phi_\sigma(x)]\}/2\ , \qquad (2)$$

where the Bose fields (for both $\nu = \rho, \sigma$) are defined by $\phi_\nu/\theta_\nu = i(\pi/N)\sum_{k\neq 0} e^{ikx}[\nu_+(k) \pm \nu_-(k)]\Lambda(k)/k$, where ϕ_ν are the number fields and θ_ν the current fields. The charge (holon) and spin (spinon) number fluctuations are defined as $\rho_\tau(k) = \sum_\sigma \rho_{\tau,\sigma}(k)$, and $\sigma_\tau(k) = \sum_\sigma \sigma\rho_{\tau,\sigma}(k)$. This type of Bose representation provides a non-perturbative description of the conduction electrons in terms of[8] holons and spinons. We will neglect for the moment all the rapidly oscillating (umklapp) terms. These will give a contribution only at half filling, i.e. $n_c = n_f$, and will be analyzed later on. Thus, the bosonized form of DKLM is:

$$\begin{aligned} H &= \frac{v_F}{4\pi}\sum_{j,\nu}\left\{\Pi^2_\nu(j) + [\partial_x\phi_\nu(j)]^2\right\} + \frac{J}{2\pi}\sum_j[\partial_x\phi_\sigma(j)]S^z_j \\ &+ \frac{J}{4\pi\lambda}\sum_j\{\cos[\phi_\sigma(j)] + \cos[2k_F j + \phi_\rho(j)]\}\left(e^{-i\theta_\sigma(j)}S^+_j + \text{h.c.}\right) \\ &- \frac{J}{2\pi\lambda}\sum_j \sin[\phi_\sigma(j)]\sin[2k_F j + \phi_\rho(j)]S^z_j\ . \end{aligned} \qquad (3)$$

This equation has the same form as for a standard Kondo lattice[3,4] except *i)* we have to keep in mind that the impurity spin, i.e. terms containing S_j^z, S_j^+ and S_j^-, contributes only if there is an f spin at site j, and *ii)* the even cutoff function $\Lambda(k)$, defined in Eq. (2), satisfying $\Lambda(k) \approx 1$ for $|k| < 1/\lambda$ and $\Lambda(k) \approx 0$ otherwise, is needed in the Bose fields to ensure that delocalized conduction electrons are described. Delocalization is essential to describe ferromagnetism,[4,5] since ferromagnetism in the Kondo lattice models is due to the double exchange, which only requires that $N_c < N_f$.[10]

In this situation each electron has on average more than one localized spin to screen, and since hopping between localized spins is energetically most favorable for electrons which preserve their spin as they hop, this tends to align the underlying localized spins.[10] This also means that double exchange will vanish if the distance between impurity spins is larger than λ. At lengths beyond λ the electrons will behave as collective density fluctuations, as usual in one dimensional systems.[8] Hence, λ measures the effective range of the double exchange, and in principle it is a function of J, n_c and n_f.

The most straightforward method to determine an ordering of the localized spins is by applying a unitary transformation $\tilde{H} = e^{\hat{\mathrm{S}}} H e^{-\hat{\mathrm{S}}}$. We choose the transformation which changes to a basis of states in which the conduction electron spin degrees of freedom are coupled directly to the localized spins: $\hat{\mathrm{S}} = i \frac{J}{2\pi v_F} \sum_j \theta_\sigma(j)\ S_j^z$. We perform the unitary transformation up to infinite order, so there is not any artificial truncation error generated (for details see Ref. 4). In the new transformed basis the double exchange interaction leading to ferromagnetism is clearly exhibited and we obtain the effective Hamiltonian for the localized spins:

$$\begin{aligned} H_{\mathrm{eff}} &= -\frac{J^2}{2\pi^2 v_F} \sum_{i,j} \frac{\lambda}{\lambda^2 + (i-j)^2}\, S_i^z S_j^z \\ &+ \frac{J}{2\pi\lambda} \sum_i \{\cos[K(i)] + \cos[2k_F i]\} S_i^x \\ &- \frac{J}{2\pi\lambda} \sum_i \sin[K(i)] \sin[2k_F i] S_i^z\ . \end{aligned} \tag{4}$$

The $K(i)$ is a term introduced by the unitary transformation, which counts all the S_i^z's to the right of the site i and subtracts from those to the left of i: $K(i) = (J/2v_F) \sum_{l=1}^{\infty} (S_{i+l}^z - S_{i-l}^z)$. This term gives the crucial difference between KLM and DKLM, as will be explained later on. The most important term in Eq. (4) is the first one, which clearly shows that a ferromagnetic coupling emerges for DKLM. This coupling is non-negligible for $N_c < N_f$ and $i - j \le \lambda$ and its strength will decrease with increasing distance between impurity spins.

For $N_c < N_f$, the physical picture given by Eq. (4) will be crucially different if the lattice of impurity spins contains *commensurate* or *incommensurate* array of holes. Hence, we analyze these two cases separately. If we have a *commensurate* doping of the impurity spins, then we can approximate the ferromagnetic term in the usual way by taking $\approx 1/n_f$ for the shortest average distance between f spins: $\{J^2 n_f^2 \lambda/[2\pi^2 v_F(1+n_f^2\lambda^2)]\} \sum_i S_i^z S_{i+1/n_f}^z$. Lattice sites which are not occupied by f spins are inert and do not contribute to the ferromagnetic phase. This was verified by DMRG: the calculated $f-f$ spin correlation functions behave similarly as those of the normal KLM. The empty sites are inert. The f-structure factor has the usual peak at $k/\pi = N_c/N_f$ for low J, hence in the commensurate case the DKLM behaves similarly to the standard KLM model.

To understand the behavior of the second and third term from Eq. (4), we notice that $K(i)$ is vanishingly small for the commensurate case, as the number of f impurity spins to the left and to the right of a given site i is the same. So the effective Hamiltonian will reduce to the random transverse field Ising model, as in the KLM.[4] The randomness is generated by $(1+\cos[2k_F i])$ at large distances and it is driven by a cosine distribution, similarly to spin-glasses.[11] To determine the phase transition we need the dependence $\lambda = \lambda(J, n_c, n_f)$, which however is very difficult to determine and as such we use the low density value $\lambda \approx \sqrt{2/J}$ close to criticality, similarly to previous works.[4,12] In this way we obtain the critical phase transition line to be: $J = \pi \sin(\pi n_c/2)/[1 - \pi \sin(\pi n_c/2)/n_f^2]$, which represents a quantum order - disorder transition with variable exponents.[4] However, this ferromagnetic phase disappears for larger distances between impurities because, as mentioned earlier, the double exchange interaction vanishes if the average distance between impurity spins, $1/n_f$, is larger than λ. This is very important because it ensures that the single impurity limit, $n_f \rightarrow 0$, is free of ferromagnetism, as it should be.

The *incommensurate* case is more difficult than the commensurate case. The reason is that in the low concentration limit the properties of DKLM will be very much dependent on the random distribution of f spins. We may observe phase separation or clusterization processes in this case. In this limit, where the average distance between impurities is very large, then the single impurity[2] approximation seems natural. However, if we look at small doping of f electrons only, then the main difference compared to the commensurate limit studied previously is that the $K(i)$ term, in Eq. (4), is not negligible anymore. The impurity f spins are no longer equally distributed to the left and right of a given site i, hence

$K(i) \approx (-1)^i (J/2v_F)$, which gives rise to a staggered field. The properties of Eq. (4) are then given by the staggered field Ising model, which gives an antiferromagnetic ordering. This antiferromagnetic ordering of the impurity spins represents a new element in DKLM compared to the Kondo lattice. This corresponds to the soliton lattice obtained by Schlottmann in a dynamical mean-field treatment of the three dimensional dilute Kondo lattice.[13]

Similar behavior also occurs above half-filling, i.e. $N_c > N_f$, where double exchange (as shown previously) does not appear. But bosonization still works: the effective Hamiltonian reduces to the second and third terms of Eq. (4), from which the most dominant term, for low doping of impurity spins, as in the case described previously, is a staggered S_i^z field. As the first term in Eq. (4) is missing in this case, the only fluctuation which can destroy a locked staggered order is S_i^x. For large J ($4 \lesssim J$) the staggered order wins. While for smaller values of J the systems will be disordered.

As we approach half filling from both sides, the bosonization approach breaks down as the strongly oscillating (umklapp) fields start dominating. The DKLM will undergo a metal-insulator transition as in a standard quantum sine-Gordon model[14] by dynamical mass generation. A Spin gap will also appear. This can be understood easily, because the half filled DKLM is equivalent to the quarter filled periodic Anderson model, which has a antiferromagnetic order.[12] The only difference from the Kondo lattice is that the massive solitons obtained for DKLM are of Su, Schrieffer and Heeger type.[15]

To confirm the previously obtained magnetic phases, we performed non-Abelian DMRG analysis of the DKLM model in the commensurate case, for both the $N_c < N_f$ and $N_c > N_f$, where ferro- and antiferromagnetism, respectively exist. For the $N_c < N_f$ case, we have investigated several commensurate dilution patterns of the form: "$0\ 0\ f\ 0\ 0\ f\ 0\ 0\ f\ \ldots$"; "$0\ f\ 0\ f\ 0\ f\ 0\ f\ \ldots$"; and "$0\ f\ f\ 0\ f\ f\ 0\ f\ f\ \ldots$" in a 64-site long chain. While in the $N_c > N_f$ limit we have studied the $n_f = 0.8$ localized spin filling (to be in accordance with the bosonization requirement of low dilution) on a 80-site long DKLM chain, i.e., we investigated the pattern: "$0\ f\ f\ f\ f\ 0\ f\ f\ f\ f\ f\ \ldots$".

These patterns were selected in such a way that the chain middle-point reflection symmetry was preserved to accelerate the calculations. There was only one exception: the "$0\ f\ 0\ f\ 0\ f$" chain has an impurity in the middle: "$0\ f\ 0\ f\ f\ 0\ f\ 0$", but its effect is rather small compared to our final errors and so it was neglected.

In the DMRG calculations careful error and convergence analysis were used, and we extrapolated the energy linearly to zero truncation error (we saw no quadratic terms large enough to affect the fit). For each given dilution pattern, filling N_c/N_f, and interaction constant J, we used several DMRG sweeps of between 200 and 400 $SO(4)$-symmetric states.

For $N_c < N_f$ ferromagnetism appears at large J values, see Fig. 1. A point on the phase diagram shown in Fig. 1 is judged to be ferromagnetic if the extrapolated energy of the spin $S_{\max}$ run is lower than the spin zero energy. This energy difference to the spin singlet excited state can be calculated directly using the $SO(4)$ basis set of the non-Abelian DMRG. The phase transition line can be determined with high accuracy if one plots the energy gap between the spin $S_{\max}$ and spin zero states as a function of J - the gap rapidly decreases as the transition is approached. It should be mentioned that, as well as in the standard Kondo case,[5] there also exists additional ferromagnetic phases inside the paramagnetic region for dilute Kondo chains.

In the opposite limit, i.e., $N_c > N_f$, we have confirmed the existence of antiferromagnetism by calculating the spin structure factor $S(k)$. As can be seen in Fig. 2, for small J and away from half filling the peak in $S(k)$ is at $2k_F$ (similarly to KLM[5]), i.e., the DKLM is a disordered paramagnet. The dominant $2k_F$ backscattering processes are manifest of a system of free localized spins embedded in effective fields determined by conduction electron scattering. The half filled case, i.e., $n_c = 1$ as in the KLM model[17] is always an antiferromagentic insulator. The tendency of Kondo lattice models to form an antiferromagnetic insulator at half filling for any nonzero J is a consequence of the Kondo effect.[17] As we increase J, the distinctive antiferromagnetic peak at $k = \pi$ appears away from half filling (see Fig. 2). As we further increase J the $2k_F$ peak broadens and decreases in strength while the antiferromagentism becomes more robust, at $J = 5$ it appers already at $n_c \approx 0.925$.

In conclusion, we have studied the dilute Kondo lattice model in one dimension both numerically, using DMRG, and analytically, with a standard bosonization approach. We have derived an effective Hamiltonian for the f spins, which accounts for the appearance of a ferromagnetic phase seen with a commensurate dilution pattern of the impurity spin array. The paramagnetic-ferromagnetic phase transition shifts to higher coupling J values as the f-spins of the chain are diluted, in agreement with the numerical DMRG calculation. We have also shown that for incommensurate dilution or above half filling, i.e., $N_c > N_f$ for low doping of impurity spins, antiferromagnetism is found. This distinguishes the dilute Kondo lattice model from the standard Kondo lattice model.
